# Adsorptive removal of Cr(VI) from water using silver nanoparticle modified-diatomite nanocomposite

Girma Gonfa<sup>1,2,3</sup>✉, Alem Kidanu<sup>1</sup>, Sumia Akram<sup>4</sup>✉, Basant Lal<sup>5</sup>, Gulmira Kezembayeva<sup>6</sup>, Dmitry Olegovich Bokov<sup>7,8</sup>, Alireza Asghari<sup>9</sup>✉, Krishna Kumar Yadav<sup>10,11</sup>, Anbalagan Saravanan<sup>12</sup> & Ahmad Hosseini-Bandegharaei<sup>9</sup>✉

Keeping the sustainability concept in view, the present study aimed to valorize diatomite for adsorptive removal of Cr(VI) ions from waters and wastewaters. A modified diatomite nanocomposite was prepared via its impregnation with silver nanoparticles, using a one-pot technique, and the silver nanoparticles-diatomite nanocomposite potency was comprehensively investigated for Cr(VI) adsorption. The raw diatomite and silver nanoparticles-diatomite nanocomposite were characterized via XRD, SEM, and BET techniques. A statistical technique, based on response surface method, was exploited for finding the optimized conditions for adsorption. Accordingly, a maximal chromium sorption of 94.0% was observed at pH 4.61, sorption duration 60.37 min, and adsorbent dosage 2 g, for an initial level of 45 mg/L for the composite adsorbent. The equilibrium scrutinization shows that Langmuir isotherm model has a better fitness with the adsorption data. In addition, the adsorption kinetic analyses demonstrated the best fit to the pseudo-second order equation and multiple distinct phases of intraparticle diffusion for both adsorbents. Overall, silver nanoparticles-diatomite nanocomposite showed excellent properties for adsorption of Cr(VI) ions and could be exploited as an adsorbent in full-scale treatment plants.

**Keywords** Diatomaceous earth, Nanomaterials, Wastewater treatment, Hexavalent chromium, Adsorption

Water is one of the most vital resources for sustaining human life and maintaining ecological balance<sup>1</sup>. Despite its abundance, challenges such as contaminations threaten access to safe and clean water globally<sup>2,3</sup>. A significant concern is water pollution by heavy metals, including lead, cadmium, arsenic, chromium, etc. Heavy metals are persistent in the environment, are toxic, and tend to bioaccumulate in aquatic organisms, posing serious health risks<sup>4</sup>. For example, chromium contamination levels in some industrial-impacted water bodies have been reported to be between 0.50 and 1.14 ppm<sup>5,6</sup>, which exceed safe limits established by health authorities. The World Health Organization recommended a maximum allowable concentration of 50 µg/L for chromium in drinking water to prevent adverse health effects<sup>7</sup>. Chromium is extensively used across various industries, including electroplating, ferrochrome production, pigment manufacturing, and leather tanning. Effluents from these industries often release chromium compounds into the environment, causing significant pollution issues. Of particular concern is hexavalent chromium (Cr(VI)), classified as a Group A carcinogen, which is

highly toxic and poses carcinogenic risks to humans upon exposure<sup>7</sup>. These factors reveal the critical need for effective treatment technologies to remove chromium from water sources to safeguard human health and the environment.

Several technologies have been developed for chromium removal from water, each with distinct advantages and drawbacks. Chemical reduction/precipitation is a traditional, cost-effective method with high removal efficiency, even up to 99.6%<sup>8</sup>. However, it generates sludge which needs careful disposal, posing environmental challenges<sup>9</sup>. Adsorption methods offer versatile and cost-effective treatment with efficiencies which are sometimes nearly complete removal depending on the adsorbent, such as activated carbon, natural minerals, or nanomaterial-enhanced sorbents, and are favored for ease of operation, regenerability, and sustainability<sup>10</sup>. Ion exchange can offer selective and efficient removal (e.g. more than 95%), particularly valuable for producing high-purity water, yet initial resin costs and fouling issues limit its use<sup>11,12</sup>. Membrane filtration achieves very high removal (up to even more than 99%) and compact systems suitable for advanced treatment, but suffers from high energy demands, fouling, and capital costs<sup>13</sup>. Photocatalytic reduction provides an eco-friendly alternative, enabling simultaneous reduction and removal of Cr(VI)<sup>14</sup>, though it requires controlled UV light and complex operation. Electrochemical treatment is effective and minimizes waste but is constrained by energy consumption and electrode maintenance<sup>14</sup>. Overall, adsorption process is proven to have comparatively lower operating costs, easy operation, and less secondary disposal products as waste<sup>15</sup>. In this context, adsorption-based methods have gained increasing attention due to their simplicity and effectiveness in the rapid treatment of wastewater containing high levels of toxic pollutants<sup>16</sup>, such as chromium<sup>17</sup>. However, adsorption performance depends on the nature of the adsorbents<sup>15,16</sup>. The research community has been looking for the development of highly efficient sorbents with an affordable cost<sup>18</sup>. So far, different natural adsorbents, such as zeolite, clays, biopolymers, and diatomite, have been studied for their merits in adsorption processes towards the removal of different heavy metal contaminants and other pollutants<sup>19–23</sup>.

Natural adsorbents have emerged as versatile and sustainable materials widely applied in various systems for the removal of pollutants from water, wastewater, and environmental matrices<sup>1,24</sup>. Due to their abundant availability, eco-friendliness, and cost-effectiveness, natural adsorbents such as diatomite, clays, zeolites, chitosan, and agricultural residues have gained significant attention in water treatment<sup>24,25</sup>. Such materials demonstrate noteworthy adsorption capacities attributable to their high surface area, porous structures, and functional groups, which facilitate strong interactions with diverse contaminants, including heavy metals, dyes, pharmaceuticals, and organic pollutants<sup>26,27</sup>. The inherent biodegradability and/or potential for chemical or physical modification enhance their performance and reusability, positioning natural adsorbents as promising candidates in the advancement of green and cost-efficient environmental technologies.

Diatomite (DE) is a highly porous, lightweight, silicon-containing soft rock that is formed by the accumulation of fossilised diatom residues. Diatomite contains mostly SiO<sub>2</sub> (50–90%) and lesser amounts of Al<sub>2</sub>O<sub>3</sub>, CaO, and Fe<sub>2</sub>O<sub>3</sub>, in addition to minor components, such as Na<sub>2</sub>O, SO<sub>3</sub>, V<sub>2</sub>O<sub>5</sub>, TiO<sub>2</sub>, and MnO<sub>2</sub><sup>28</sup>. DE has been previously investigated for the adsorption of chromium from water<sup>28–30</sup>. Because of its high adsorption effectiveness, which is possibly ingrained in excess oxygen bridges, coordination defects, and a large number of surface silicon hydroxyl groups that have significant affinities for different contaminants, it has shown great promise as an adsorbent for a variety of pollutants<sup>28</sup>. Recent studies indicate that nanomaterial-modified diatomite is receiving increased attention due to its key properties, including a large specific surface area, high adsorption capacity, and excellent stability<sup>21</sup>. When adding nanoparticles to the structure of most adsorbents, agglomeration frequently occurs, reducing the surface area and, as a result, the adsorption capacity<sup>31</sup>. However, in the case of diatomite, its abundant surface silicon hydroxyl bridges may interact with metals or metal oxides, potentially preventing agglomeration and may result in substantial adsorptive performance improvement. Previously, nickel/nickel oxide<sup>32</sup>, niobium(v) oxide<sup>31</sup>, iron oxide<sup>33</sup>, and manganese oxide<sup>34</sup> modified diatomite adsorbents were studied for the adsorptive removal of Cr(VI) from water.

This study explores the innovative use of silver nanoparticle-modified diatomite as an effective adsorbent for the removal of hexavalent chromium (Cr(VI)) from aqueous solutions. Previous research has demonstrated the enhanced Cr(VI) adsorption capabilities of activated carbon coated with silver nanoparticles<sup>35</sup>. Therefore, the current work designed to take the advantages of the dual functionality of silver nanoparticles, since not only do they significantly improve adsorption efficiency, but they also facilitate the reduction of toxic and highly mobile Cr(VI) to the less toxic and more stable trivalent chromium (Cr(III))<sup>7,36</sup>. Such reduction represents a cost-effective and environmentally favorable strategy for chromium remediation<sup>36</sup>. Addressing a critical gap in current adsorbent development, the present work innovatively integrates silver nanoparticles within a purified and thermally treated diatomite matrix through impregnation. The sequential purification of raw diatomite via nitric acid treatment and thermal calcination ensures an optimized substrate, which upon modification with silver nanoparticles, exhibits superior performance in Cr(VI) removal. This novel composite combines the inherent adsorption properties of diatomite with the catalytic and reductive advantages of silver nanoparticles, presenting a compelling advancement in sustainable wastewater treatment technologies.

## Experimental Materials

Raw diatomite was obtained from Adami-Tulu, Oromia region, Ethiopia. HNO<sub>3</sub> (65%), silver nitrate (99%), HCl (37%), diphenyl carbazide, LiBO<sub>2</sub>, HF, KBr, and potassium dichromate (K<sub>2</sub>Cr<sub>2</sub>O<sub>7</sub>) obtained from Merck were used as received. All the chemicals used in the study are of reagent grade and were exploited without any further purifications.

Diatomite adsorbent Preparation

The raw diatomite (RDE) was pre-treated by chemical treatment with nitric acid, followed by thermal calcination, adopting a previously reported procedure with some modifications<sup>37</sup>. The RDE sample was crushed and washed with pure distilled water by mixing at 500 rpm for 30 min. Then, it was leached using 2 M HNO<sub>3</sub> with a solid-to-liquid ratio of 1:10 (g/mL) at 120 °C with continuous mixing at 500 rpm for 8 h. The acid-treated diatomite was filtered and washed several times with deionized water till the pH of the washing water reached 7.0. Further, it was dried in an oven at 100 °C for 24 h. The dried sample was then ground and sieved with a 45 µm sieve. The acid-treated diatomite was finally calcinated in a muffle furnace at different temperatures (500, 600, and 700 °C) for 4 h. The thermally processed diatomite (PDE) was kept in a sealed container until further use.

Composite adsorbent Preparation

The nanocomposite adsorbent was synthesized using the in-situ reduction method, using previously reported conditions, with some modifications<sup>38</sup>. For this purpose, 500 mL of a 35 mM AgNO<sub>3</sub> solution was prepared using deionized water. PDE (60 g) was mixed with the AgNO<sub>3</sub> solution and subjected to heat at 60 °C for 5 h to attach silver ions to the surface of diatomite structures. Then, the silver nanoparticles (AgNpS) modified diatomite was dispersed in 1.0 L of deionized water for 10 min, and filtered to remove the non-attached silver ions. Afterwards, 50 mL of 35% tri-sodium citrate was added drop by drop to the resulting solution and was kept for 1 h at 25 °C to form the silver nanoparticles-diatomite (AgNps-DE) nanocomposite. Finally, the nanocomposite was recovered through filtration and dried in an oven at 100 °C for 3 h.

Characterizations

Compositions of raw diatomite (RDE) and modified diatomite (PDE) were carried out using atomic absorption spectroscopy (Analyst 700 Perkin-Elmer AAS). The samples were fused in LiBO<sub>2</sub> and dissolved in HF, and then characterized by atomic absorption spectroscopy. X-ray powder diffraction (XRD) analysis for diatomite was taken using x-ray diffractometer (D8 VENTURE, Bruker Systems, Japan). The XRD pattern was set to obtain a 2θ range of 5.0–80.0. The specific surface area of the prepared samples has been determined using a Brunauer-Emmett-Teller instrument (SA-9600 series, HORIBA, USA). The morphological characteristics of the diatomite were studied using field emission scanning electron microscopy (Inspect Instruments, F50 SEM, Japan). By digesting the sample with HNO<sub>3</sub>, the amount of AgNps immobilized on the PDE was measured and calculated using the previously described methodology<sup>38,39</sup>.

Adsorption study

The adsorption performances of the PDE and AgNps-DE were studied at Cr(VI) initial concentrations (10–30 mg/L), adsorbent concentration (5–30 g/L), temperature (25–55 °C), adsorption times (30–120 min), and solution pH (4.0–8.0) using batch adsorption process. In all the batch experiments, 100 mL of Cr(VI) aqueous solution was transferred to 250 mL glass flasks, and predetermined nanocomposite samples (0.5, 1, 2, and 3 g) were added to Cr(VI) solution. Then, the solutions were stirred using a magnetic stirrer. Finally, the Cr(VI) concentration in water was determined by exploiting a UV-VIS spectrophotometer (JASCO V770, Oxford Instruments, UK) at 540 nm using the colorimetric method with the 1,5-diphenylcarbazide complex at a pH of 1.0 using the method previously reported<sup>4,30</sup>. The Cr(VI) removal efficiency were calculated using from the correlation given in Eq. (1).

Cr (VI) removal efficiency (%) = (C<sub>0</sub> - C<sub>t</sub>) / C<sub>0</sub> × 100 (1)

In this equation, C<sub>0</sub> and C<sub>t</sub> are the initial Cr(VI) and final Cr(VI) concentration, respectively, in mg/L.

Response surface methodology

In recent times, a software-developed numerical model that generates the relationship among the selected key factors and the response through response surface methodology (RSM) has gained more interest for process model development and optimization of the process<sup>4,40</sup>. In this study, RSM-based Box-Behnken design (BBD) was used to develop the model and generate response surfaces to evaluate the effect of selected process variables (pH, agitation duration, and dosage of adsorbent) on the Cr(VI) removal. The selected key factors and their corresponding ranges were determined from the preliminary screening experiments, which are depicted in Table 1. In this study, as per BBD, a total of 17 experimental runs were performed, and among them, there were 5 centre points. The different combinations of parameters were used to conduct the adsorption experiments, and the response surface model and model analysis were performed using Design Expert (Version 13.0, Stat-Ease

Factors	Symbol	Unit	Level		
			Lower value (−1)	Middle	Upper value (+1)
pH	A	–	2	5	8
Reaction time	B	min	60	90	120
Adsorbent dose	C	g/100 mL	0.5	1.25	2

Table 1. The factors and their corresponding ranges used to generate the BBD combination.

Inc., USA). A second-order polynomial equation was fitted to establish the relationship between the factors and response as shown in Eq. (2).

$$CY = \beta_0 + \sum \beta_i x_i + \sum \beta_{ii} x_i^2 + \sum \beta_{ij} x_i x_j \quad (2)$$

where, Y denotes the response, that is, Cr(VI) removal (%),  $x_i$  denotes the selected variable (pH, contact time, and adsorbent dose), and  $\beta_i$  refers to the corresponding coefficient. An analysis of variance (ANOVA) was applied to analyze the suitability of the model. The 3-D response surface curves were generated to visualize the interaction effects of the selected factors on the Cr(VI) removal. Further, a second-order model correlating the factors and responses was developed, and then it was statistically verified.

### Adsorption isotherm

Adsorption isotherm analysis provides a good understanding of what may be happening while carrying out the processing of adsorption. In this work, adsorption isotherm data were acquired for both PDE and AgNps-DE. The adsorption experiments were conducted using various quantities of adsorbent (0.5, 1, 2, and 3 g). The experiments optimum conditions obtained from the Response Surface Methodology. At equilibrium, the amount of Cr(VI) that was adsorbed into the prepared adsorbent (mg/g), denoted as  $q_e$ , was estimated using Eq. (3).

$$q_e \text{ (mg/g)} = \frac{(C_0 - C_e) \times V}{m} \quad (3)$$

where,  $C_0$  and  $C_e$  are the initial and equilibrium concentration of Cr(VI) (mg/L), respectively.  $m$  is the mass of the sorbent (g), and  $V$  is the volume of Cr(VI) solution (L). From the adsorption results, the data were fitted to various isotherm models.

### Adsorption kinetics

To appraise sorption data towards kinetic analysis, 100 mL aqueous solution having 20 mg/L Cr(VI) was taken into 250 mL flasks. In each flask, 1.0 g of adsorbent was added. The solutions were continuously mixed with a magnetic stirrer, keeping the pH value at 4.0 and the temperature at 35 °C. The concentrations of Cr(VI) in the aqueous solution were measured at different times and fitted to various kinetic models.

## Results and discussion

### Characterizations

#### Diatomite compositions

The compositions of RDE and PDE are reported in Table 2. In general, the chemical composition of diatomites can be classified into three categories: main, secondary, and minor<sup>28</sup>. Silica is a major diatomite component, followed by secondary components, such as aluminum oxide, iron oxide, and calcium oxide. The minor components are represented by other metal oxides, such as MgO, Na<sub>2</sub>O, K<sub>2</sub>O, SO<sub>3</sub>, V<sub>2</sub>O<sub>5</sub>, TiO<sub>2</sub>, MnO<sub>2</sub>, and some organic and inorganic compounds. For the current raw diatomite (RDE), silica content was found to be 75.8%, while the contents of Al<sub>2</sub>O<sub>3</sub> and Fe<sub>2</sub>O<sub>3</sub> were 7.3% and 3.6%, respectively. The silica content of the current diatomite is slightly lower than the value previously reported by Weldemariam et al.<sup>41</sup> for a diatomite sample taken from the same area, that is, the Adami Tulu area of Ethiopia. In general, the silica content of this deposit is in the range reported for most deposits from different countries (Table 2). It also has a lesser loss of ignition, that is, lower in organic content and carbonates. The secondary components (Al<sub>2</sub>O<sub>3</sub> and Fe<sub>2</sub>O<sub>3</sub>) and minor components are also in the range reported for raw diatomite from different countries. Table 3 shows the comparison of composition for raw diatomite (RDE) and diatomite thermally treated at 600 °C. The composition of silica was found to

**Table 3.** Chemical composition (wt%) of Raw diatomite (RDE) and treated diatomite (PDE).

rise under chemical and thermal treatments, whilst the composition of the majority of secondary and minor elements tended to decrease. While the calcination procedure removes moisture and organic contaminants, the acid treatment may result in the reduction of metal oxides<sup>42</sup>.

The amount of silver nanoparticles loaded on the treated diatomite was determined by acid digestion using AAS. It was found that the amount of silver loaded on diatomite was 28 mg/g. The value is in the range (24 to 46.6 mg/g) of AgNps loading on diatomite previously reported by Panáček et al<sup>39</sup>. The amount of AgNps attached to the diatomite in the current work was observed to be higher than the value reported (0.537 wt%) by Xia et al<sup>38</sup>. This variation could be due to the differences in the AgNps-DE pre-processing techniques and other parameters, such as initial AgNps concentration and mixing conditions.

#### SEM and XRD analyses

The SEM images of the RDE, PDE, and AgNps-DE composite are displayed in Fig. 1. The SEM image of the RDE had a more compacted structure with some areas of uniform porous spots (Fig. 1 (a<sub>1-2</sub>)). A complicated porous structure made up of fragmented, overlapping frustules is shown in the micrograph. As is typical of diatomite, these frustules have a large surface area, uneven forms, and porous channels. The SEM images of the PDE became more churned due to removing impurities from the diatomite structure, as shown in Fig. 1 (a<sub>1-2</sub>). In addition, the surface of PDE seemed to be smooth due to the removal of the impurities by chemical and thermal treatments. Sharper edges and clearer pore outlines are visible at closer range, indicating that both organic and inorganic contaminants have been eliminated. Moreover, certain morphological alterations or partial deterioration of the frustule edges can be observed for the treated diatomite, which could be due to thermal treatment at high temperatures. Although some of the frustules seem slightly crumpled or fragmented, the porous architecture is still visible. The SEM image of AgNps-DE composite in Fig. 1 (c<sub>1-2</sub>). Diatom frustules appear structurally intact and well-preserved upon impregnation with silver nanoparticles, displaying distinctive porous walls and ornamentation. Effective acid leaching and thermal treatment are indicated by the surface's cleanliness and sharpness. Small bright spots or clusters could represent AgNps distributed on or within the pores of the frustules.

The XRD spectrum of RDE, PDE, and AgNps-DE is shown in Fig. 2. The XRD spectra of the RDE, PDE, and AgNps-DE had broad peaks ranging between 12 and 33° with a diffused peak, indicating that RDE, PDE and AgNps-DE were less ordered and less crystalline. The minor crystalline phases that are indicated at 2θ of 26° and 27° may correspond to kaolinite and quartz. The XRD results of the current diatomite are consistent with the results reported for samples collected from different locations<sup>44-46</sup>. Acid and thermal treatment slightly reduced the kaolinite and quartz as the corresponding peaks diminished. It can also be observed that the chemical and thermal treatment, as well as the impregnation of silver nanoparticles on its structure, did not change the amorphous nature of the diatomite.

#### BET surface areas

The BET surface areas of the RDE, PDE, and AgNps-DE were determined using the BET surface analyzer and are depicted in Table 4. The current BET value (17.4) for the RDE was found to be in good agreement with the value (20 m<sup>2</sup>/g) reported by Weldemariam et al<sup>41</sup>. for the sample collected the sample from the same area. However, the BET area of the treated diatomite in this work was much higher than the value (maximum value of 29.0 m<sup>2</sup>/g) reported by Weldemariam et al<sup>41</sup>. In this work, the sample calcinated at 600 °C showed a maximum surface area (56.0 m<sup>2</sup>/g). This may be due to the application of a combination of both HNO<sub>3</sub> and thermal treatment. The BET surface area of treated DE was also comparable with the values reported for treated DE from some regions, such as Iran (57 m<sup>2</sup>/g)<sup>42</sup>. However, it is lower than the value reported for other regions, such as Egypt (195 m<sup>2</sup>/g)<sup>37</sup>. Further, the incorporation of AgNps in the diatomite structure slightly reduced in BET surface area to 39 m<sup>2</sup>/g, as shown in Table 4. This could be related to the reduction of pore sizes in the diatomite structure due to the impregnation of AgNps. The BET result is in good agreement with the SEM images.

#### Adsorption studies

Before examining how adsorption parameters affect the efficiency of Cr(VI) removal, the performance of Cr(VI) removal was compared for RDE, PDE, and AgNps-DE composite under fixed conditions. To do this, 1.0 g of each adsorbent (RDE, PDE, and AgNps-DE) was added to 100 mL of 10 mg/L Cr(VI) aqueous solution at pH 4.0 and 25 °C and continuously mixed for 1.0 h. According to the results, the removal efficiencies of Cr(VI) for RDE, PDE, and AgNps-DE were 43, 50, and 85%, respectively. As expected, the higher adsorption by the AgNps-DE might be due to the active functional groups related to silver nanoparticles, which could enhance the interaction of the composite with the dissolved Cr(VI) ions<sup>47,48</sup>. Therefore, for further adsorption studies, PDE and AgNps-DE were used and compared.

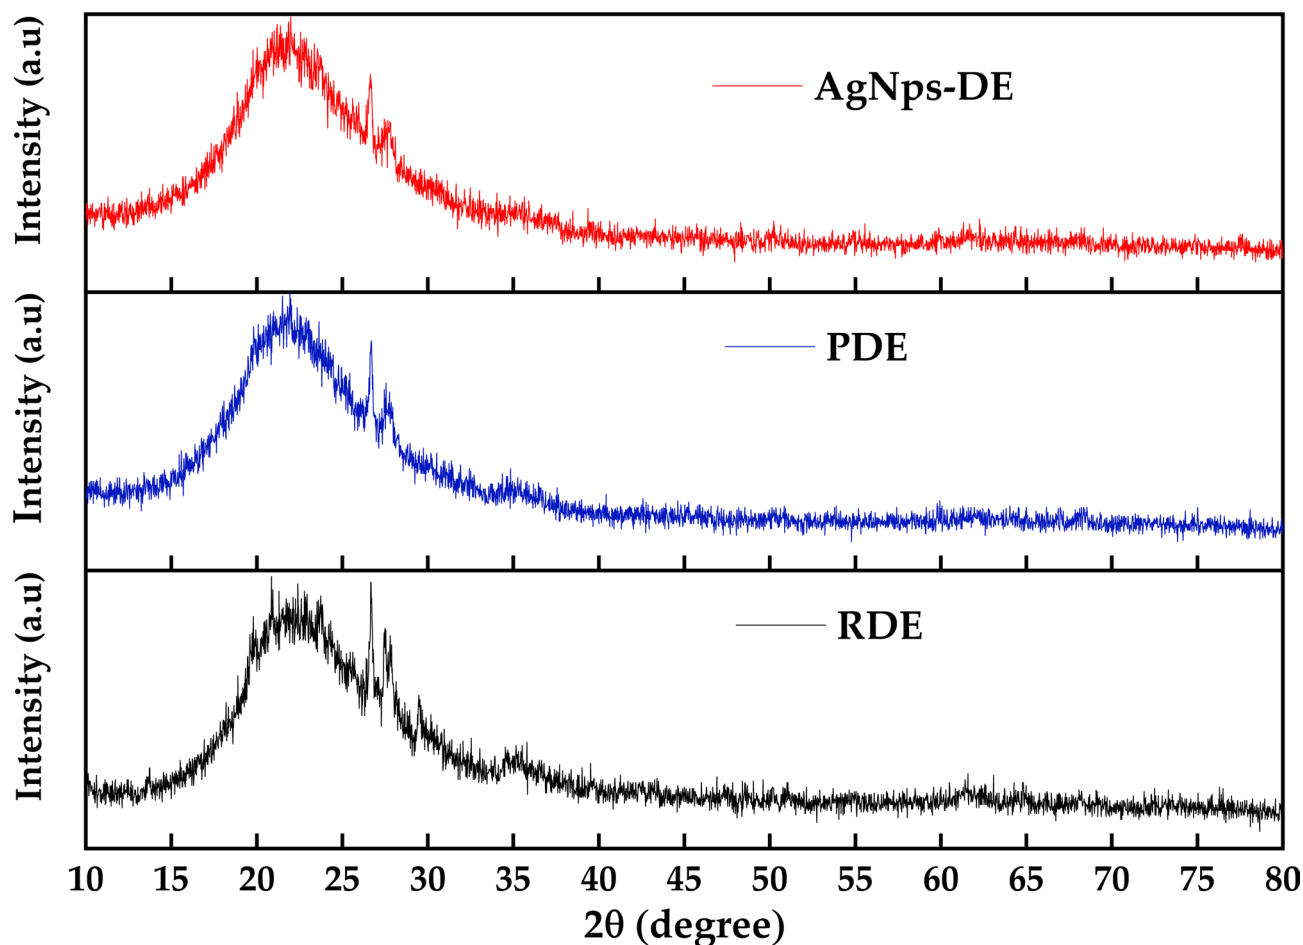

**Fig. 1.** SEM images. (a<sub>1–2</sub>) RDE, (b<sub>1–2</sub>) PDE, and (c<sub>1–2</sub>) AgNps-DE composite.

#### *Effect of pH*

The influence of pH on the adsorptive removal of chromium (Cr (VI)) is depicted in Fig. 3(a). In this experiment, 1.0 g of each adsorbent (PDE and AgNps-DE) was added to 100 mL of Cr(VI) aqueous solution of 10 mg/L Cr(VI) and mixed for 100 min at 25 °C. The solution pH was varied from 2 to 8 by adjusting with NaOH and HCl. The results show that maximum removal percentages of 66.3% and 95.8% for PDE and AgNps-DE, respectively, at a solution pH of 4.0. Hence, in comparison to PDE, the AgNps-DE composite shows better Cr(VI) removal efficiency. It is apparent that the pH of the media affects the adsorbent's surface charge, ionization degree, and speciation of the chromium ions<sup>49</sup>. As is well known, depending on the pH of the solution, chromium can exist in a variety of anion forms, including  $\text{HCrO}_4^-$ ,  $\text{Cr}_2\text{O}_7^{2-}$ , and  $\text{CrO}_4^{2-}$ . Hence, at pH 1.0 to 4.0,  $\text{HCrO}_4^-$  can be the dominant form of hexavalent chromium in solution<sup>50</sup>.

As media pH increases from 2.0 to 4.0, the removal percentage of both PDE and AgNps-DE increases and reaches 66.3% and 95.8% for PDE and AgNps-DE, respectively. At lower pH values, the surface of diatomite might be positively charged since silanol (Si-O) and Si-O-Al groups on the diatomite surfaces are protonated due to the existence of excess  $\text{H}^+$  in the medium, blocking the chromate ions from adsorption on the surface<sup>49,51</sup>. Increasing the solution pH may result in deprotonation of the active adsorbent site, which may increase the chromium metal adsorption on the sites<sup>49,52</sup>. In the case of the lower concentration range, the ratio of the initial

**Fig. 2.** XRD pattern of raw diatomite (RDE), treated diatomite (PDE) and silver-diatomite composite (AgNps-DE).

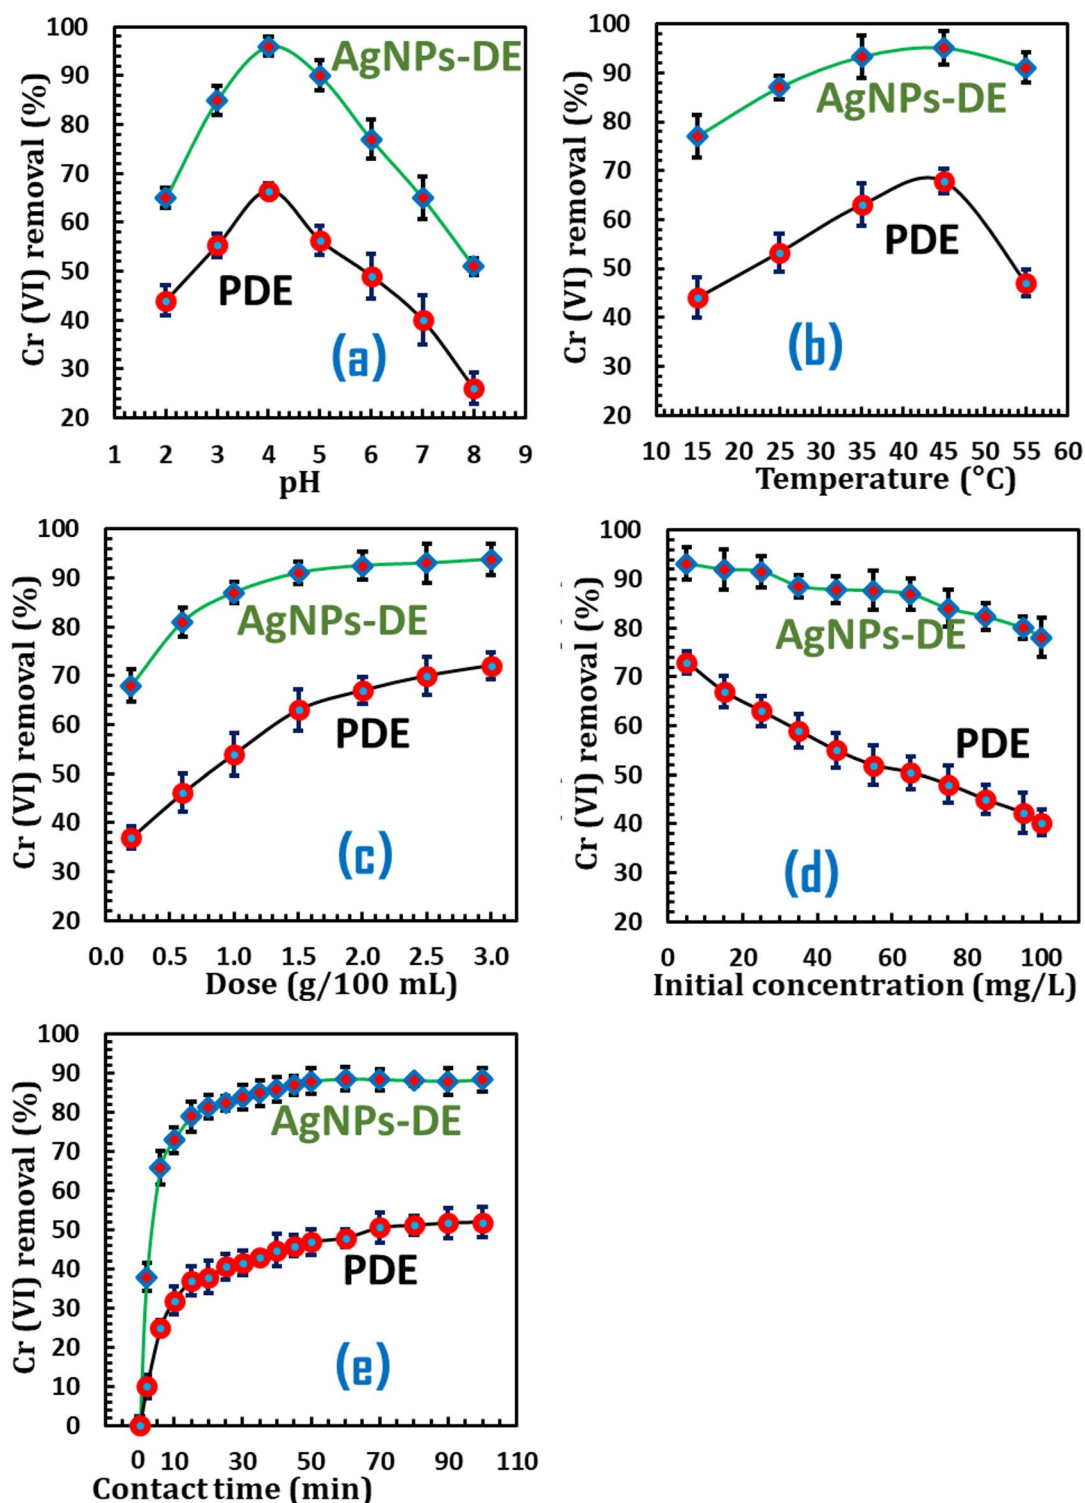

Sample		BET (m <sup>2</sup> /g)
RDE		17.4
PDE calcinated at different temperatures	500 °C	46.0
	600 °C	56.0
	700 °C	52.7

**Table 4.** BET specific surface area of RDE, PDE and AgNps-DE. AgNps-DE nanocomposite.

number of adsorbate to the available sorption sites is low, and the sorption becomes independent of initial concentration, which enables the complete ions<sup>19</sup>. That is, the competition between excess hydrogen ions and Cr(VI) species to attach contact with the active sites of adsorbents reduces the absorption of Cr(VI)<sup>53</sup>. On the other hand, the formation of dihydrogen chromate could also exist from Cr(VI) species at lower pH<sup>54</sup>. Further increase in the pH gave rise to the decline in Cr(VI) removal. This could be attributed to the loss of active sites of the adsorbent and changes in Cr(VI) species<sup>49</sup>.

#### *Effect of temperature*

To examine the effect of temperature on adsorption, the experiment was carried out using 100 mL aqueous solutions containing 50 mg/L of Cr(VI) at a pH of 4.0, employing 1.0 g of adsorbents in each test. The solutions were mixed continuously for 100 min, and the temperature was varied from 15 to 55 °C. The effect of temperature on Cr(VI) removal is illustrated in Fig. 3(b). From the results, the adsorptive removal of Cr(VI) increased with temperature from 15 to 45 °C for both adsorbents, reaching 67.1 and 95.2% for RDE and AgNps-DE, respectively. The increase in temperature enhances the kinetic energy of the particles, which brings about the migration of ions from the bulk fluid into the surface of the adsorbent, and then into the pores of the adsorbent to interact with the active sites<sup>55</sup>. This was in agreement with previously reported works on the effect of temperature on the adsorption of Cr(VI) with various adsorbents<sup>20</sup>. Nevertheless, further increments in temperature resulted in a

**Fig. 3.** Effect of various factors on Cr(VI) removal. (a) effect of pH, (b) effect of temperature, (c) effect of adsorbent dosage, (d) effect of initial Cr(VI) concentration, and (e) effect of adsorption time.

decline removal of Cr(VI) which led to the support of desorption of Cr(VI) which reduced the net absorption of the Cr ions<sup>53</sup>.

#### Effect of adsorbent dosage

To examine the impact of adsorbent dosage on Cr(VI) removal, 100 mL of Cr(VI) aqueous solution containing 50 mg/L of Cr(VI) was tested at a pH of 4.0, 25 °C for 100 min. To check the impact of adsorbent dosage on

adsorptive removal of Cr(VI), different dosages (0.2 g to 2 g) of PDE and AgNps-DE were added in each flask. The results are depicted in Fig. 3(c). As can be seen from Fig. 3(c), while the adsorbent dosage increased from 0.2 to 3 g, the removal efficiency of Cr(VI) was also found to be increased for both adsorbents. The maximal adsorptive removal of Cr(VI) was 72.1% and 93.9% for PDE and AgNps-DE, respectively. The Cr(VI) removal can be increased with adsorbent dosage, which is directly related to the availability of adsorption sites<sup>56</sup>. Hence, the rate of removal of Cr(VI) gradually declined with the adsorbent dosage, that is, the lower removal efficiency obtained at lower adsorbent dosage, while an increment in Cr(VI) removal was found at higher adsorbent dosage.

Effect of initial Cr(VI) concentration

To study the effect of initial Cr(VI) concentrations, 100 mL of aqueous solution with various levels of Cr(VI) (5 to 100 mg/L) was tested by adding 1.0 g of adsorbent. The pH was adjusted to 4.0, and adsorption studies were conducted at 25 °C for 100 min. The result is shown in Fig. 3(d). As the initial level (Cr(VI) concentration increased from 5 to 100 mg/L, the Cr(VI) removal increased to 40.3 and 78.1% for PDE and AgNps-DE, respectively. A further increase in Cr concentration was found to result in a decline in the removal efficiency. An increase in the initial Cr(VI) concentration can strengthen the driving force needed to overcome mass transfer resistance, thereby facilitating the adsorption from the aqueous solution onto solid supports<sup>55</sup>. However, when the concentration exceeds a certain value, the adsorption capacity of Cr(VI) declines because of the limited availability of the active sites. In such a way, the adsorption status was decided by considering the amount of available active sites till they were saturated<sup>56</sup>.

Effect on adsorption time

The effect of contact time on the adsorptive removal of Cr(VI) was studied using 100 mL aqueous chromium solution with 50 mg/L Cr(VI) by adding 1.0 g of adsorbents (Fig. 3(e)). It was demonstrated that the removal of Cr(VI) increased with contact time. In case of AgNps-DE, the removal of Cr(VI) dramatically increased from 0 to 75% as the contact time increased from 0 to 20 min; however, for PDE, it increased from 0 to 40% in 50 min. In the first 20 min, the adsorption was rapid due to free sites on the adsorbent surface for Cr(VI) binding<sup>57</sup>. A rapid increase in Cr(VI) removal was observed during the initial stage; however, the rate of removal gradually declined after 50 min for AgNps-DE and 70 min for PDE, likely due to the saturation of available surface sites.

Experimental design and statistical analyses

The effect of three selected factors, that are, adsorption time, dosage of adsorbent, and solution pH, on the adsorptive removal of Cr(VI) by AgNps-DE was investigated by applying the Response Surface Method based on BBD. AgNps-DE was selected for optimization of the adsorption parameter because it showed better adsorption efficiency. A total of 17 experimental runs were conducted to develop the response surface model. Accordingly, 2nd order polynomial equation was established that provides a relationship between the three selected independent factors and the Cr(VI) removal as a response. The statistical fitness of the response surface quadratic model was analyzed by analysis of variance (ANOVA), the same is depicted in Table 5. In this regard, the terms are represented as quite significant while the p-value is found to be less than 0.05. As per ANOVA, the calculated p-value for the main and interaction parameters was observed to be low enough, with the R<sup>2</sup> value, 0.977. It shows that the generated model was very good at representing the relation between the adsorptive removal of Cr(VI) and the selected factors affecting the adsorption performance. In addition, for the significance of the overall model, the F-value of 75.75 and p-value less than 0.05 showed it is significant. The quadratic equation representing the relationship between the selected independent variable and the response is given in Eq. (14).

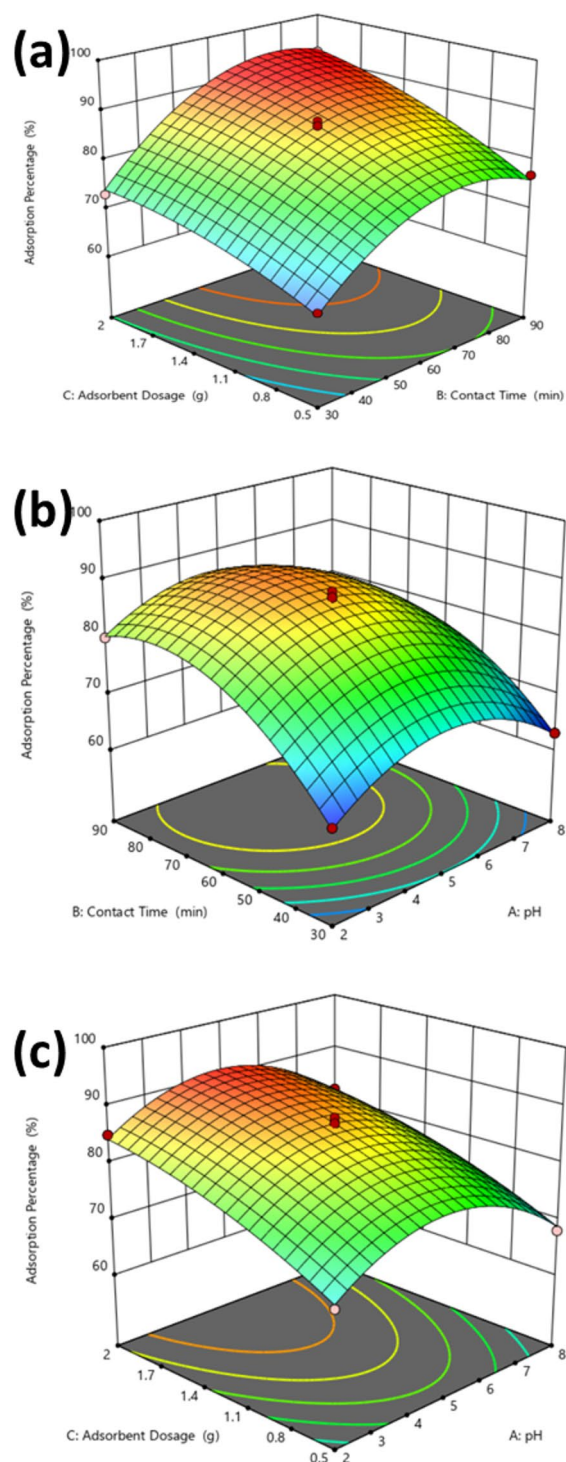

$$Y = +87.00 + -1.25A + 7.50B + 6.50C - 1.25 AB - 0.2500 AC + 1.75BC - 8.63 A^2 - 8.12 B^2 - 2.13C^2 \quad (4)$$

Table 5. ANOVA results for the acquired quadratic model.

where, Y is the Cr(VI) removal percentage, A is the solution pH, B is the contact time (min), and C is the adsorbent dosage (g/100 mL).

Figure 4 shows the developed response surface plots that represent the relationship of Cr(VI) removal with selected parameters. Figure 4(a) shows that the percentage of Cr(VI) removed rises as the adsorbent dosage increases from 0.5 to 2 g. At the same time, it was found that the Cr removal increased with contact duration as it increased from 30 to 60 min. However, when we increased the adsorption time further, the capacity to remove Cr(VI) was nearly constant. As pH rises from 2.0 to 5.0 and the adsorption period increases from 30 to 60 min, the percentage of Cr(VI) elimination increases (Fig. 4 (a)). However, a further increase in pH and adsorption

time reduces the adsorption of Cr(VI). Cr(VI) adsorption increases with rising adsorbent dosages at a lower pH value, and a further increase in pH was found to reduce adsorption. From the statistical analysis, the maximum Cr(VI) removal of 92% was predicted at adsorption time, 60 min; pH value, 5.0; adsorbent dosage, 2 g; and initial level of Cr(VI), 45 mg/L.

### Kinetics study

To investigate the kinetic aspects and interactions between Cr (VI) and adsorbents, adsorption kinetics was adopted to analyze the relationship between Cr (VI) removal and elapsed time. In this context, various kinetic models are utilized, specifically the nonlinear pseudo-first-order (NPFO), nonlinear pseudo-second-order (NPSO), and intra-particle diffusion models, to assess the goodness-of-fit of experimental adsorption data (Fig. 5a). The following indices were used for evaluations:

$$R^2 = 1 - \frac{\sum (q_{e,exp} - q_{e,cal})^2}{\sum (q_{e,exp} - q_{e,mean})^2} \quad (5)$$

$$R^2_{Adj} = (1 - R^2) \times \left( \frac{n - 1}{n - p - 1} \right) \quad (6)$$

$$\Delta q(\%) = 100 \sqrt{\frac{1}{N - 1} \sum_{i=1}^N \left( \frac{q_{exp} - q_{cal}}{q_{exp}} \right)^2} \quad (7)$$

$$\chi^2 = \sum_{i=1}^N \left( \frac{(q_{e,exp} - q_{e,cal})^2}{q_{e,cal}} \right) \quad (8)$$

$$HYBRID = \frac{100}{N - P} \sum_{i=1}^N \left[ \frac{q_{e,exp} - q_{e,cal}}{q_{e,exp}} \right] \quad (9)$$

where,  $q_{e,exp}$  and  $q_{e,cal}$  are, respectively, the experimental and predicted capacities (mg/g),  $q_{e,mean}$  is the average amount of the experimental adsorption capacity (mg/g),  $p$  is the number of parameters in models, and  $n$  is the number of experimental data. The highest goodness-of-fit is of the model with highest value of  $R^2_{adj}$  and  $R^2$ , and lowest amounts for other indices.

The pseudo-second-order kinetic model proved to be more appropriate for describing the sorption process of Cr (VI) for both adsorbents, as Table 6 illustrates. This model indicates that, for both PDE and AgNPs/DE, the interaction of Cr(VI) ions with the adsorbents' sorption sites is the rate-controlling stage in the overall adsorption mechanism<sup>58,59</sup>. This conclusion was further validated by testing the Ritchie kinetic model. The Ritchie's equation can be given as:

$$q_t = \frac{q_e K_R t}{1 + K_R t} \quad (10)$$

where,  $q_t$  is the sorption capacity (mg/g) at any time ( $t$ ), and  $K_R$  is the constant of Ritchie ( $\text{min}^{-1}$ ). The assessments (see Fig. 5a; Table 6) showed that the Ritchie model also affirms that the adsorption process has a second-order nature, again indicating that the interaction of Cr(VI) ions with the adsorbents' adsorption sites is the rate-controlling step. However, the results in Table 6 show that the value of  $k_2$  (the constant of pseudo-second order kinetic model) for AgNPs/DE ( $4.61 \text{ min}^{-1}$ ) was much greater than that of PDE (2.66), which shows the higher rate of adsorption of Cr (VI) for AgNPs-DE, compared to DE.

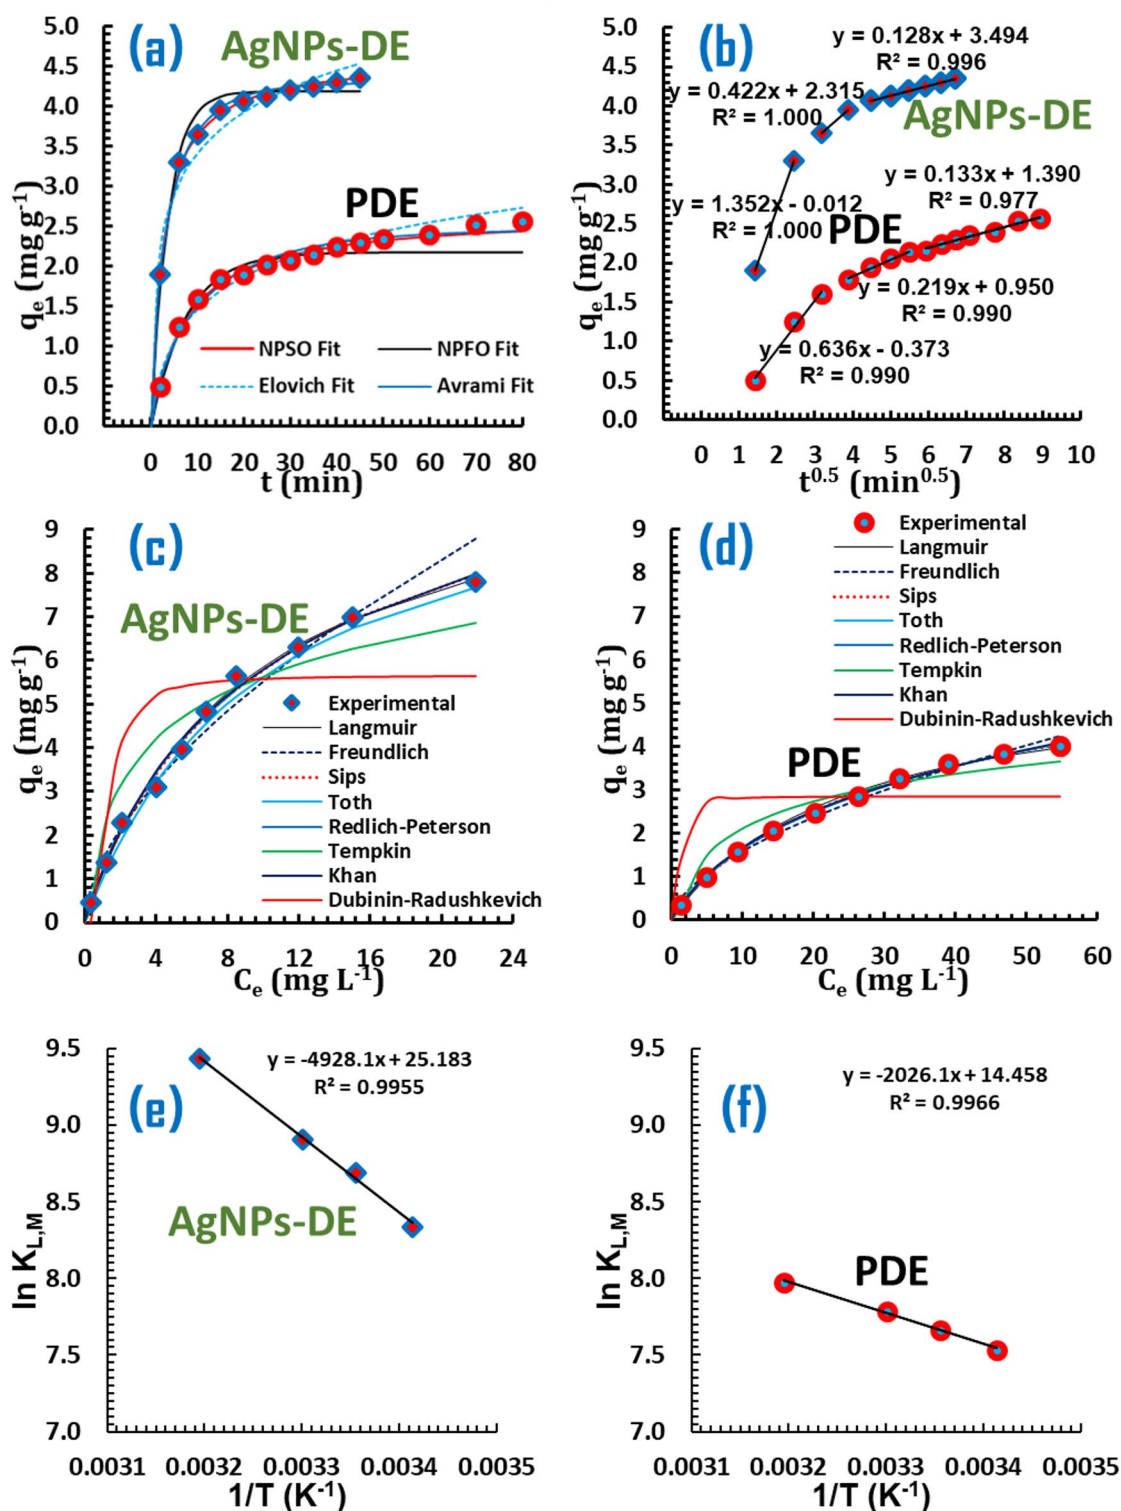

In addition to the above kinetic models, two other models (Elovich and Avrami models) were also fitted with the data. These models can be given as the following equations, respectively:

$$q_t = \frac{1}{\beta} \ln(\alpha \beta t) \quad (11)$$

$$q_t = q_e (1 - e^{-(K_{av} t)^{n_{av}}}) \quad (12)$$

In these equations, the initial adsorption rate is represented by  $\alpha$  (mg/g.min), while  $\beta$  (g/mg) indicates the degree of surface coverage and the activation energy associated with chemisorption.

Moreover, the Avrami kinetic constant is denoted as  $k_{AV}$  (1/min), and  $n_{AV}$  refers to a fractional order of adsorption that corresponds to the specific adsorption mechanism. The results (Fig. 5a; Table 6) showed that the finesses of the Elovich and Avrami models are not as good as pseudo-second order (NPSO) and Ritchie models. Nevertheless, inspecting the values of  $n_{AV}$  for both AgNPs/DE and DE adsorbents, 0.247 and 0.091, respectively, shows that they lie between 0 and 1, revealing the possibility that the adsorption process is primarily governed by diffusion<sup>60</sup>. Consequently, the intraparticle diffusion model's multilinearity was tested. As can be observed, the plots illustrated in Fig. 5b show the presence of multilinearity for the intraparticle diffusion model, indicating the presence of multiple distinct phases in the adsorption processes of Cr (VI) on both AgNPs/DE and DE adsorbents (Table 6). The graph shows that the initial phases, marked by rapid adsorption on the external surface, are completed within the first 6 (for AgNPs/DE) and 10 (for DE) min. This is followed by a controlled intraparticle diffusion phase (step 2), which lasts from 6 to 20 min for AgNPs/DE and from 10 to 30 min for AgNPs/DE). After this period, the equilibrium adsorption phase (stage 3) begins, occurring after 50 min (for

AgNPs/DE) and 90 min (for DE). The values of intercepts for the first stage (in both cases) are negative, which underscores the probability of external surface adsorption and film diffusion control in the very initial steps of adsorption of Cr (VI) on both AgNPs/DE and DE adsorbents<sup>61</sup>.

### Adsorption isotherm studies

The adsorption equilibrium of Cr(VI) onto both AgNPs-DE and PDE was investigated and compared through the application of various two-parameter adsorption isotherm models, viz. the Langmuir, Dubinin-Radushkevich (D.R.), Freundlich, and Temkin isotherms. The Langmuir isotherm is predicated on the assumption of monolayer adsorption occurring at homogeneously distributed adsorption sites that exhibit uniform affinity for the Cr (VI) ions<sup>62,63</sup>. In contrast, the Freundlich isotherm model claims that adsorption occurs in multilayers on a heterogeneous adsorbent surface, characterized by varying affinities among sorption sites<sup>62,64</sup>. The Temkin isotherm, on the other hand, assumes a linear decrease in the heat of adsorption with increasing surface coverage, indicating a uniform distribution of binding energies that reflects sorbent-solute interactions<sup>65</sup>. Figure 5d illustrates the fitting of experimental data to non-linear representations of the Langmuir, D.R., Freundlich, and Temkin adsorption isotherms for Cr (VI) adsorption on both AgNPs-DE (Fig. 5c) and PDE (Fig. 5d), and Table 4 reports the obtained parameters and values of statistical indices (Eqs. (14)–(17)). In addition, the mentioned figures (Figs. 5c and d) demonstrate the visual fitness of isothermal studies with the following three parameters, which were exploited for a better understanding of the equilibrium aspect of Cr (VI) adsorption on AgNPs-DE and PDE.

Redlich-Peterson isotherm:

$$q_e = \frac{K_{RP} C_e}{1 + a_{RP} C_e^g} \quad (13)$$

Khan isotherm:

$$q_e = \frac{q_s b_K C_e}{(1 + b_K C_e)^{a_K}} \quad (14)$$

Toth isotherm:

$$q_e = \frac{q_m K_T C_e}{[1 + (K_T C_e)^n]^{1/n}} \quad (15)$$

Sips isotherm:

$$q_e = \frac{q_m (K_S \cdot C_e)^{1/n}}{1 + (K_S \cdot C_e)^{1/n}} \quad (16)$$

where  $q_e$  and  $q_m$  are the equilibrium and theoretical maximal capacities, respectively, and other parameters have been introduced in the literature elaborately<sup>58,66</sup>.

Based on the results shown in Table 6, among the two-parameter models, the Langmuir isotherm seems to be able to provide a successful theoretical framework for understanding the adsorption of Cr(VI) onto both adsorbents, establishing a relationship between the amount of Cr(VI) adsorbed (in mg/g) and its equilibrium concentration in solution (in mg/L). This model has been effectively employed to describe adsorption equilibria in various single- and multi-component systems<sup>67</sup>. For AgNPs-DE, the Langmuir constants,  $q_m$  and  $K_L$ , were determined to be 10.99 mg/g and 0.11 L/mg, respectively, which are considerably higher than those of PDE (i.e., 5.76 mg/g and 0.04 L/mg). These results demonstrate that both the adsorption capacity and the affinity of AgNPs-DE are higher for Cr (VI) adsorption, compared with PDE.

Among the three-isotherm models, the Sips model showed better fitness with the equilibrium results (see Table 6), even in comparison to the Langmuir model. The Sips isotherm model integrates the Langmuir and Freundlich adsorption isotherms, offering a comprehensive framework for understanding adsorption behavior for adsorbates. At low concentrations, the Sips model converges to the Freundlich isotherm, reflecting the heterogeneous nature of the adsorption sites. Conversely, at elevated concentrations, it approaches the Langmuir isotherm, which characterizes monolayer adsorption capacities<sup>60</sup>. In the current work, the  $n$  values (obtained from Sips model) for both AgNPs-DE and PDE are close to unity. Based on such findings reported by Sajjadi et al.<sup>68</sup> and Pérez-Marín et al.<sup>69</sup>, the isothermal analysis suggests that, along with Sips model, the Langmuir isotherm provides the most accurate representation of this Cr (VI) adsorption process on both AgNPs-DE and PDE. These findings indicate that the adsorption of Cr (VI) ions onto both AgNPs-DE and PDE conforms to a monolayer adsorption model characterized by homogeneous coverage.

### Thermodynamic aspects and adsorption mechanisms

In addition to the above comparisons, thermodynamic parameters aspects governing the adsorption processes of Cr (VI) on two adsorbents were also examined to compare the mechanism of adsorption on pre-treated diatomite (PDE) with that on silver nanoparticles modified diatomite (AgNPs/DE). The Van't Hoff equation was used to clarify the nature of adsorption and the underlying mechanisms<sup>70,71</sup>.

Temperature	Thermodynamic parameters					
	$\Delta G^\circ$ (kJ/mol)		$\Delta H^\circ$ (kJ/mol)		$\Delta S^\circ$ (J/mol.K)	
	PDE	AgNPs/DE	PDE	AgNPs/DE	PDE	AgNPs/DE
288.15	-18.35	-20.31	16.84	41.21	120.20	209.37
298.15	-18.97	-21.53				
308.15	-19.61	-22.44				
318.15	-20.76	-24.54				

**Table 7.** Thermodynamic parameters of Cr(VI) adsorption on PDE and AgNPs-DE.

$$\ln K_C = -\frac{\Delta H^\circ}{R} \times \frac{1}{T} + \frac{\Delta S^\circ}{R} \quad (17)$$

By the aid of Van't Hoff equation (the above relation), one can plot  $\ln K_C$  versus  $1/T$  (Kelvin<sup>-1</sup>) and obtain enthalpy change ( $\Delta H^\circ$ ; J/mol) from the slope and entropy change ( $\Delta S^\circ$ ; J/mol.K) from the intercept. In Eq. (18),  $R$  is the gas constant, and  $K_C$  is obtained from the isothermal data at different temperatures and the Sips (or Langmuir) constants, which are the best isotherms for describing the equilibrium adsorption of Cr (VI) on both studied adsorbents. The derivation of the needed dimensionless thermodynamic constant was obtained from the following relation<sup>58</sup>.

$$K_C \text{ (dimensionless)} = 1000 \times K_L \times AW_{Cr} \quad (18)$$

where,  $K_L$  is the isotherm constant at the studied temperatures (288.15, 298.15, 308.15, and 318.15) and  $AW_{Cr}$  is the molecular weight of the Cr element. Also, the change in Gibbs free energy ( $\Delta G^\circ$ ), can be obtained from the following relation:

$$\Delta G^\circ = \Delta H^\circ - T \Delta S^\circ \quad (19)$$

The related plots were shown in Fig. 5e and f, and the thermodynamic results were summarized in Table 7.

The results indicate that the adsorption of Cr (VI) on PDE is primarily a physicochemical process, supported by the enthalpy change value (16.84)<sup>58</sup>, which suggests that physicochemical interactions, such as ion-exchange, play a significant role in this type of adsorption. The endothermic nature of the process, indicated by a positive  $\Delta H^\circ$  is aligned with findings from adsorption of Cr(VI) removal by Pinecone biochar<sup>72</sup>, amino-functionalized palm oil fibres<sup>73</sup>, etc. In contrast, the adsorption of Cr (VI) on AgNPs/DE is associated with a high positive  $\Delta H^\circ$  value (41.21), which reveals that chemisorption has a great share in the process, though a part of Cr (VI) may still be adsorbed by the physicochemical mechanisms like ion-exchange. The presence of silver nanoparticles enhances the reduction potential, facilitating electron transfer between Cr (VI) ions and the AgNPs. This interaction results in a stronger binding affinity, as evidenced by a high positive  $\Delta H$  (and lower  $\Delta S^\circ$  value), suggesting that chemical adsorption occurs during the adsorption process. The reduction of Cr (VI) to less toxic forms, such as Cr (III), is a critical aspect of this mechanism, highlighting the dual role of AgNPs as both adsorbents and reducing agents<sup>74</sup>. In addition, the calculated values for  $\Delta G^\circ$  were negative for both adsorbents, indicating spontaneous adsorption under the studied conditions. However, the magnitude of  $\Delta G^\circ$  was significantly lower for AgNPs/DE, compared to PDE, reinforcing the fact that chemisorption on AgNPs/DE is more predominant. Such findings not only contribute to our understanding of Cr (VI) removal from waters and wastewaters but also underscore the potential advantages of using nanomaterials for adsorption purposes.

## Conclusions

The comprehensive studies in the current work demonstrated the efficiency of silver nanoparticles-modified diatomite (AgNps-DE) for the removal of chromium (VI) from aqueous solutions. The effects of selected parameters, such as adsorption time, solution pH, dosage of adsorbent, and initial concentration of Cr(VI) were investigated on the removal of Cr(VI) by both Ag nanoparticle-modified diatomite (AgNps-DE) and pretreated diatomite (PDE) and compared with each other. In all cases, the AgNps-DE performance was superior to PDE. The incorporation of silver nanoparticles significantly enhanced the adsorptive capacity, achieving a maximum removal efficiency of 94% under optimized conditions: a pH of 4.6, an adsorption time of 60.4 min, and an adsorbent dosage of 2 g at an initial Cr(VI) concentration of 45 mg/L. This performance outstripped that of pretreated diatomite (PDE), confirming the superior efficacy of AgNps-DE in Cr(VI) remediation. The adsorption processes were describable by the Langmuir isotherm model, indicating monolayer adsorption on homogeneous surfaces, with AgNps-DE exhibiting higher adsorption capacity (10.99 mg/g) compared to PDE (5.76 mg/g). Kinetic studies revealed that the pseudo-second-order model best described the adsorption kinetics, implying that the rate-limiting step is predominantly related to the interaction between Cr(VI) ions and the active sites on the adsorbents. The presence of multiple distinct phases in the adsorption process was confirmed through intraparticle diffusion analyses, highlighting rapid external surface adsorption followed by controlled intraparticle diffusion phases. Thermodynamic assessments indicated that the adsorption processes were spontaneous and endothermic for both adsorbents, with chemisorption playing a significant role in AgNps-DE due to the reduction of Cr (VI) facilitated by silver nanoparticles. Overall, these findings underscore the potential of AgNps-DE as an efficient and environmentally-friendly sorbent for Cr(VI) removal from

contaminated waters and wastewaters, paving the way for future applications in full-scale wastewater treatment plants.
